#### RESEARCH MEMORANDUM

#### EXPERIMENTAL INVESTIGATION OF

LAMINAR-BOUNDARY-LAYER CONTROL ON AN AIRFOIL SECTION EQUIPPED WITH SUCTION SLOTS LOCATED AT DISCONTINUITIES

IN THE SURFACE PRESSURE DISTRIBUTION

By Laurence K. Loftin, Jr., and Elmer A. Horton

#### SUMMARY

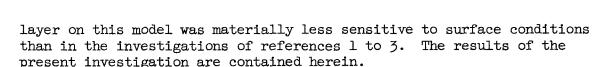

An experimental investigation has been made of a two-dimensional, 6.6-percent-thick, 6-foot-chord airfoil section equipped with suction slots for laminar-boundary-layer control. The airfoil section was designed to have favorable pressure gradients between the suction slots which were located at discontinuities in the airfoil surface pressure distribution. The upper surface contained nine slots, whereas the lower surface contained seven slots. The investigation indicated that the laminar boundary layer on this airfoil had the same extreme sensitivity to minute details of the model surface condition as has been found in other investigations of laminar-boundary-layer control.

#### INTRODUCTION

Extensive laminar boundary layers have been obtained at high Reynolds numbers by means of suction through discrete slots or porous surfaces in several wind-tunnel investigations (refs. 1 to 3). In these investigations, however, the attainment of extensive laminar boundary layers was found to be critically dependent upon minute details of the model surface condition. In an effort to decrease the sensitivity of the laminar boundary layer to minute surface imperfections, A. M. O. Smith of the Douglas Aircraft Co., Inc., designed an airfoil (designated the Douglas DESA-2) with a suction-slot arrangement which was markedly different from those employed in the investigations of references 1 and 3.

A short experimental investigation has been made in the Langley low-turbulence pressure tunnel of the Douglas DESA-2 airfoil. The purpose of the investigation was to determine whether the laminar boundary

#### MODEL AND APPARATUS

#### Model

The airfoil section employed was 6.6 percent thick, had a design lift coefficient of 0.1, and was designated Douglas DESA-2. Ordinates of the airfoil are presented in table I. The airfoil was designed in such a way that the upper- and lower-surface pressure distributions contained nine and seven pressure discontinuities, respectively. A suction slot was located at each pressure discontinuity and the pressure gradients between slots were favorable. The theoretical pressure distribution about the airfoil is shown in figure 1 and a tabulation of the theoretical-pressure-distribution data is given in table II. The number and spacing of the slots and the magnitude of the pressure gradients between the slots were chosen only after very extensive laminar-boundary-layer stability calculations had been made. These calculations covered the Görtler type of instability as well as the usual two-dimensional type of instability. The design of the model was such that stability calculations indicated the boundary layer to be exceedingly stable at

Reynolds numbers of the order of  $15.0 \times 10^6$ . These calculations also indicated a maximum Reynolds number of  $50.0 \times 10^6$  or more for which full-chord laminar flow might be expected.

The model of the DESA-2 boundary-layer suction airfoil had a 6-foot chord and was constructed of aluminum alloy. The ordinates of the model when installed in the tunnel are believed to have been within a range from about ±0.001 to ±0.002 inch of the specified ordinates. The surfaces were polished to a very high degree of smoothness. A sketch of the two-dimensional model which shows the method of construction, slot locations, and a detail of the slot shape and surface contour in the vicinity of the slot is presented in figure 2. The slot widths employed in the tests as well as the slot locations and spans are given in table III. The possibility of contamination of the slotted portions of the airfoil by turbulence originating at the spanwise ends of the slots dictated the variation in slot span with slot position. As indicated in figure 2, the slot widths could be adjusted by the plate forming the rear lip of the slot. Each slot opened into a separate compartment within the model. These compartments were connected to a variable-speed blower by ducts leading to a valve and manifold arrangement by which the flow in each slot could be adjusted. Photographs of the model installed in the tunnel and the ducting, valve, and manifold arrangements are shown in figures 3 and 4, respectively.

The quantity flow removed from each slot was measured by a calibrated orifice meter which was located in the duct leading from the model to the manifold, and the total flow removed from all of the slots was measured by a calibrated orifice meter located in the duct leading from the manifold to the variable-speed blower. A flush orifice within the chamber measured the chamber static pressure. For the rates of flow involved in the investigation, the velocities within the slot chambers were so low that the measured static pressure was assumed equal to the total pressure.

The flush orifices used to measure the airfoil pressure distribution were formed by drilling 0.005- to 0.008-inch-diameter holes in the surface of the model.

## Wind Tunnel and Test Methods

The investigation was made in the Langley low-turbulence pressure tunnel. The two-dimensional model, when installed in the tunnel, completely spanned the 3-foot dimension of the 3-foot by  $7\frac{1}{2}$  - foot test section. A complete description of the tunnel is contained in reference 4.

The position of transition on the surfaces of the model was determined through the use of a medical stethoscope. For this purpose, the stethoscope was attached to a total-pressure tube which could be inserted into the airstream through the tunnel wall at several locations. The noise levels associated with laminar and turbulent flow are markedly different so that the listener can easily distinguish between the two types of flow. Observations of the flow fluctuations within the boundary layer were made with a hot-wire anemometer. The hot wire was attached to a remotely controlled probe which permitted movement of the hot wire to different positions along and above the surface.

### RESULTS AND DISCUSSION

The initial tests consisted of measurements of the surface pressure distribution and extent of laminar flow on the airfoil at 00, 0.50, and 1.00 angle of attack. These tests were made at a Reynolds number of  $5.78 \times 10^6$ with the design flow removal in each slot. A comparison of the desired and actual flow removal from each slot is shown in figure 5 in which the flow coefficient corresponding to each slot is plotted against chordwise position. The results of the experimental surface-pressure-distribution measurements for 0° and 1.0° angle of attack are presented in figure 6. The value of the free-stream velocity employed in both the pressure coefficient and the flow coefficient has been corrected for tunnel blockage according to the method given in reference 4. A comparison of the experimental pressure distributions of figure 6 with the theoretical distribution shown in figure 1 indicates that the general character of the theoretical distribution was realized experimentally. Because of small inaccuracies in the contour of the surface and lips of the slots, however, small pressure peaks are evident in the vicinity of several of the slots. The lift coefficients corresponding to angles of attack of  $0^{\circ}$  and  $1.0^{\circ}$ were not measured, nor have the experimental pressure distributions been integrated to obtain the lift coefficients. Comparison of the theoretical and experimental pressure distributions, however, indicates that the design lift coefficient probably occurred between 0° and 1.0° angle of attack.

In the first tests at a Reynolds number of  $5.78 \times 10^6$ , full-chord laminar flow was not realized. In an effort to find the causes of transition, extensive surveys were made with the stethoscope. In addition, some hot-wire measurements of the amplitude of laminar-boundary-layer oscillations at different points along the surface were made. The effects of variations in the suction quantities and angle of attack were also investigated. In general, it was found that transition was caused by the same type of minute surface imperfections as has been found to cause transition in other investigations. The laminar boundary layer was very

sensitive to small changes in slot and surface contour and to small bits of surface roughness which passed unnoticed by the naked eye and were found only as a result of stethoscopic or hot-wire surveys. The conclusion would, therefore, seem to be that no reduction in the sensitivity of the laminar boundary layer to small surface imperfections was shown by the DESA-2 boundary-layer suction airfoil as compared with other laminar-boundary-layer control schemes which have been investigated.

The maximum Reynolds number at which full-chord laminar flow was obtained was  $5.78 \times 10^6$ . This result does not necessarily mean that extensive laminar flow could not have been obtained at higher Reynolds numbers. Any effort to obtain extensive laminar flows at higher Reynolds numbers, however, would have required the same type of painstaking attention to surface condition as described in connection with the investigation reported in reference 3. There seemed to be little point in following such a cleanup procedure in the present investigation since the question posed in the basic purpose of the investigation had already been answered.

#### CONCLUDING REMARKS

An experimental investigation has been made of a two-dimensional, 6.6-percent-thick, 6-foot-chord airfoil section equipped with suction slots for laminar-boundary-layer control. The airfoil section was designed to have favorable pressure gradients between the suction slots which were located at discontinuities in the airfoil surface pressure distribution. The upper surface contained nine slots, whereas the lower surface contained seven slots. The investigation indicated that the laminar boundary layer on this airfoil had the same extreme sensitivity to minute details of the model surface condition as has been found in other investigations of laminar-boundary-layer control.
